ABSTRACT

Composting is among the most effective integrated waste management strategies used to recycle sewage sludge (SS) waste and generate a useful product. An encapsulated lifting system is a relatively new industrial-scale composting technology. The objective of this study was to evaluate the effectiveness of composting dewatered stabilized SS mixed with green waste using this new technology. The composting process was monitored by changes in the physico-chemical properties, UV-visible spectra, and fourier transform infrared (FTIR) spectra. The composting temperature was steady in the thermophilic range for 24 and 12 d in the intensive and maturation phases, respectively, which fulfilled the disinfection requirement. Moreover, the temperature increased rapidly to 76.8°C within three days, and the thermophilic temperatures peaked twice and lasted longer than in traditional composting, which accelerated SS degradation and decreased the composting period necessary to obtain mature compost. FTIR spectroscopic analysis showed a diminished in methyl group derived from methylene C-H aliphatic groups because of organic matter degradation by microorganisms and an increased number of aromatic chains. The new technology may be a viable and sustainable alternative for SS management that converts waste into compost that is useful as a soil amendment.

environmental impacts of this SS.

Composting can help efficiently manage SS by reducing the volume and weight of initial waste by approximately 50%, as well as killing pathogenic microorganisms due to the generation of heat (50°C to 70°C) during its thermophilic phase, and producing mature and stable organic substances [4]. However, to obtain a high-quality compost product, efficient composting technologies must be used [5]. Currently, various composting technologies are available; the choice of technology depends on the operational cost, the time needed to reach compost maturity, the land availability, and the source of raw materials. In recent years, due to the demand for new SS treatment technologies, composting technologies have been subjected to considerable modifications (e.g., co-composting, vermicomposting, and windrow composting) to make composting technology more cost effective [6].

Two-stage composting is a relatively new concept in the production of compost, which integrates two completely different technologies into a single composting process in order to improve the final compost quality and increase the cost-effectiveness of the process; it also helps to minimize the negative environmental impact of traditional composting technologies. Several two-stage systems have been examined: Some systems combine two composting technologies, such as the integration of in-vessel composting with periodically turned windrow composting or the integration of vermicomposting and traditional composting methods, while other systems include some form of mechanical treatment, such as waste pre-treatment, mechanical biological treatment, or anaerobic digestion, prior to the composting process [7].

The first paper addressing the two-stage composting was by Kulikowska and Klíminik [8], who studied SS waste. The technology involves a transfer between two systems, typically a periodically turned windrow and an aerated bioreactor. The organic waste spends a short time (10 d) in the aerated bioreactor to allow decomposition and sanitation of the organic material before spending 207 d in the windrow to reach maturity. Another two-stage composting technology involves primary composting (PC) and secondary composting (SC) [9]. During PC, the thermophilic phase (50°C to 60°C) starts quickly and persists for a long period. When the temperature decreases to ambient temperature, PC is considered complete, and SC begins, during which decomposition continues, resulting in a second thermophilic phase [9]. This novel technology thus results in two thermophilic temperature peaks during the whole composting process and a longer thermophilic phase than that obtained with traditional composting (one stage with composting windrows); in addition, compared with traditional composting, the composting duration of the new method is shortened, and the quality and stability of the compost product are increased. Only 30 d are required for the production of mature compost with two-stage composting, as opposed to the 90 d to 270 d required in traditional composting [10].

González et al. [11] demonstrated the advantages of SS composting at the industrial scale by utilizing an aerated static windrow covered with a novel semipermeable film. This novel technology reduces carbon dioxide, sulphur, and nitrogen oxide emissions and also reduces the overall process time by reducing heat losses and prolonging the thermophilic phase; furthermore, by increasing the treatment capacity, this technology increases system efficiency and reduces operating costs [11]. However, the disadvantages of such systems include complex infrastructure and greater costs than required for open-windrow composting technologies.

The use of a semipermeable cover system with air-floor aeration for a mixture of SS and pruning debris green waste (GW) led to a change in the bacterial profile; microorganisms with the ability to degrade recalcitrant compounds were detected in the early stages of composting, presumably due to the high temperatures rapidly reached during the first few days of composting [12]. In a previous study, during the composting of pig manure and wheat straw using a semipermeable membrane cover with a bottom-up aeration system, the relative abundances of anaerobic *Clostridiales* and pathogenic *Pseudomonas* decreased, and the abundance of the facultative anaerobe *Cellvibrionales*, which has a complex cellulase system, increased [13]. The use of a semipermeable membrane during pig manure and wheat straw composting with a bottom-up aeration system allowed even and sufficient oxygen concentration to be achieved with a slight positive pressure, decreasing the anaerobic zone in the compost pile and decreasing methane (CH₄) emissions by 22.42% [14]. Greenhouse gases (CO₂, CH₄, and N₂O), as well as ammonia production and emissions were also decreased during cattle manure composting using a semipermeable membrane cover [15].

The encapsulated lifting system (ELS) is a relatively new composting technology that includes a two-phase aerated static windrow combined with a GORE® cover membrane and a bottom-up aeration system. However, to date, data on the use of ELS technology with a GORE® cover membrane in SS composting remain unavailable. Therefore, this study is novel, and the goal was to evaluate the effectiveness of this technology based on monitoring the changes in the physico-chemical properties and the UV-visible and Fourier transform infrared (FTIR) spectra during a SS composting process.

## 2. Materials and Methods

### 2.1. Composting Materials

The study was carried out at a composting facility at the municipal wastewater treatment plant in the city of Kecskemét, Hungary. The plant serves a population of 240,000, treats 20,000 m³/d and generates 22,400 t/y of activated SS (21-23% dm content). The composting facility was established in 2010, with its initial production capacity being approximately 5,000 m³/y.

The dewatered stabilized SS (DSSS) and GW were used for composting. The DSSS was obtained by centrifuging stabilized sludge from a biogas digester, while the GW (grass, wood chips, tree leaves, etc.) was collected from the parks and gardens in Kecskemét. The DSSS was mixed with the GW materials, which acted as bulking agents, at a 1:4 proportion of sludge to bulking agent to obtain optimum moisture and a C/N ratio of approximately 65% and 25:1, respectively. The main characteristics of the raw materials used are presented in Table 1. The DSSS was characterized by having the highest moisture and nitrogen content, while the GW had a high organic matter (OM) content and the lowest moisture content. The GW materials were thus added to lower the overall moisture content, increase the C/N ratio, and enhance the final structure of the composted material.

2.2. Composting Process

Composting processes were carried out using ELS with a GORE® cover membrane at an industrial scale (Fig. 1). The composting process consisted of two phases of aerated static windrow treatment under GORE® cover membrane: an intensive phase (4 w) and a maturation phase (3 w).

At the beginning of the intensive phase, the mixture was loaded into a composting cell; this was on day 0. The cell (35 m long, 8 m wide, and 2.6 m high, with a 730 m³ total capacity) had three reinforced concrete side walls, which were covered with GORE® cover membrane and had a dedicated ventilation system to ensure its oxygen supply. When the windrow temperature dropped to ambient temperature at day 28, the intensive phase was considered complete. At that time, the mixture was removed from the composting cell with an excavator and placed in another composting cell for the maturation phase. That cell (30 m long, 8 m wide, and 2.6 m high, with a 730 m³ total capacity) had three reinforced concrete side walls, which were covered with GORE® cover membrane, and had a dedicated ventilation system to ensure its oxygen supply. When the windrow temperature dropped to ambient temperature at day 28, the intensive phase was considered complete. At that time, the mixture was removed from the composting cell with an excavator and placed in another composting cell for the maturation phase. That cell (30 m long, 8 m wide, and 2.6 m high, with a 630 m³ total capacity) had three reinforced concrete side walls, which were covered with a GORE® cover membrane and had a ventilation system to provide adequate aeration. The maturation phase began on days 29 till 49. A 4 m high glass-fibre tarpaulin was attached to the reinforced concrete walls, and the whole structure was covered with a GORE® cover membrane during both phases to avoid excessive water loss caused by wind and evaporation. The two-stage composting process was considered complete when the temperature of the windrow declined to ambient temperature. The material was then screened using a screening drum with 12 x 12 mm holes.

The temperature was measured using Pt-100 type sensors housed in stainless-steel sheaths that were connected to a data acquisition system linked to a standard PC. The Pt-100 sensor was placed in the windrow at measuring points located at half the windrow’s height. The daily mean temperatures were calculated based on recorded hourly temperatures that were taken continuously throughout the process using a digital recorder. Another temperature sensor was placed outside to measure the ambient temperature for comparison.

2.3. GORE® Cover Membrane

The GORE® cover membrane had three different layers: An expanded polytetrafluoroethylene (ePTFE) membrane/microporous film and two protective layers made of high-robust polyester fabric that formed the laminate’s top and bottom layers. The membrane in the middle layer acted as the functional component, and the membrane parameters were as follows: water vapor permeability of ≤ 19.5 m² Pa W⁻¹, air permeability of 1.5-6.5 m³ m⁻² h⁻¹, and hydrostatic pressure of ≥ 50 kPa [15].

The GORE® cover membrane is waterproof, windproof, and reusable; the material is highly tolerant to biological and chemical degradation and to heat (up to 200-260°C) [15]. With a micropore size of approximately ≤ 0.2 μm, the membrane effectively prohibits the release of microbes, gaseous substances, and particulate matter while remaining semi-permeable to moisture [16]. Most of the water vapor generated during the early composting phase in response to decomposition of OM did not escape the membrane due to the limited permeability of the membrane, however, building up an aqueous condensate layer on the inner surface of the cover. This aqueous condensate layer acted as a scrubber for odours by dissolving odour compounds and forming droplets that returned the compounds to the composting material where they could be further decomposed by microorganisms.

2.4. Ventilation System

Air was supplied via ventilators and trenches placed at the base of the windrow. These trenches acted as ducts to provide air to the windrow and to collect leachate from the windrow. Aeration was accomplished by ventilators with a maximum flow rate of 2,400 m³/h at 2,940 rpm and 80 dB(A), using a forced aeration system placed at the base of the windrow. The ventilator engine power was 2.5 kW. A ventilation system controlled by a timer was used to control the windrow temperature. The injected flow rate diffused the air intermittently. In the intensive phase, the aeration frequency was 491 min/d (491 min ON/949 min OFF), and the air flow rate was 172 m³ air/m³ compost/d, while in the maturation phase, the frequency was 404 min/d (404 min ON/1,036 min OFF), and the air flow rate was 166 m³ air/m³ compost/d.

2.5. Sampling Strategy and Collection

Composting was conducted for 49 d. Homogenous 1-kg samples that represented the average conditions of the entire windrow were collected in accordance with the US Composting Council standard [17] at the following intervals: 0 (first day of composting/initial non-decomposed material), 7, 14, 21, and 28 d during the intensive phase, and 35, 42, and 49 d during the maturation phase.
2.6. Physicochemical Analysis of Compost Samples

Ash content was determined by burning samples (previously dried at 105°C) at 550°C for 7 h in a muffle furnace [17]. OM were estimated as follows [19]:

\[ \text{OM} (%) = 100 - \text{ash} (%) \]  

A 1:10 aqueous extract of fresh compost was used to analyse the pH and electrical conductivity (EC), as described by Guo et al. [18]. Losses of OM due to OM mineralization were calculated based on the initial and final ash content for each time interval according to the equation [19]:

\[ \text{OMloss} (%) = 100 - 100 \left( X_1(100 - X_2) / [X_2(100 - X_1)] \right) \]  

where \( X_1 \) and \( X_2 \) are the initial and final ash concentrations, respectively. Total nitrogen (TN) and total carbon (TC) were determined by subjecting air-dried samples to dry combustion at a combustion temperature of 1,100-1,200°C using a CNS analyzer (Fisons NA 1500 Series II CNS analyzer). The cation exchange capacity (CEC) of the air-dried samples was determined according to Harada and Inoko [20]. The ammoniacal nitrogen (NH\(_4\)^+-N) and nitrate nitrogen (NO\(_3\)^-N) were extracted by mixing air-dried samples with 0.5 M K\(_2\)SO\(_4\) at a ratio of 1:10 (w/v), mechanically shaking for 1 h, and filtering through 0.45-μm membrane filters. The filtrate was used for NH\(_4\)^+-N and NO\(_3\)^-N determination using the colorimetric method, as described by Okalebo et al. [21].

2.7. UV-visible Spectroscopic Analysis

UV-visible spectroscopy analysis was performed according to the following method by Zbytniewski and Buszewski [22]. One gram of air-dried compost and 50 mL of 0.5 M NaOH were shaken for 2 h and then centrifuged at 3,000 rpm for 25 min. The absorbance of the supernatant was measured at \( \lambda = 280 \) nm (\( A_{280} \)), 472 nm (\( A_{472} \)), and 664 nm (\( A_{664} \)) using a UV-2000 spectrophotometer covering a frequency range of 200 nm to 800 nm. The following absorbance ratios were calculated: \( E_{280} = A_{280}/A_{664} \), \( E_{472} = A_{472}/A_{664} \), and \( E_{664} = A_{672}/A_{664} \).

2.8. FTIR Spectroscopic Analysis

Air-dried samples from each composting step were analyzed with a Bruker DRIFT (diffuse reflection infrared fourier transform) FTIR spectrometer covering a frequency range of 4,000-400 cm\(^{-1}\). The resolution was set to 4 cm\(^{-1}\), and 32 scans were recorded before being averaged for each spectrum and corrected against ambient air, which acted as the background.

2.9. Statistical Analyses

The data shown in the tables and figures represent the means of three replicate subsamples for each composite sample with standard deviations calculated using Microsoft Excel 2016. Each set of three subsamples was prepared from the corresponding composite sample (representing the average conditions of the entire windrow in question) and analyzed independently.

3. Results and Discussion

3.1. Temperature Evolution

The composting process is principally a biological phenomenon that relies highly on temperature fluctuations within windrows. In this case, the mixture of DSSS and GW at the beginning of the composting process was characterized by its large fermentable fraction. On day 0 (the start of the intensive phase), the temperature began to rise rapidly from 31.2°C, reaching a peak temperature of 76.8°C within three days (Fig. 2). These temperatures were higher and increased faster than those observed during composting of the same substrate using classical methods [23, 24]. The micropositive pressure environment resulting from the joint effects of the forced bottom-up ventilation system and the GORE(R) cover membrane was conducive to providing the even supply of sufficient oxygen to microorganisms that is required to degrade OM. Ultimately, the microbial degradation of easily decomposable OM was enhanced, the decomposition rate increased, and a large amount of heat produced. After peaking during the intensive phase, the temperature decreased, remaining in the mesophilic range (below 42°C) between days 25 and 31. The decrease in temperature can be explained by two main phenomena: the exhaustion of the initial simple molecules and the development of conditions hostile to microorganism activity.

![Fig. 2. Evolution of temperature during SS-GW composting.](image)
and that humification resumed, demonstrating that the compost was stable and that the process could be considered complete. This phenomenon of two thermophilic peaks has been observed by several authors [26-28]. Zhang et al. [9] subjected raw materials to a two-phase composting process comprised of primary fermentation and secondary fermentation during which a thermophilic phase was attained twice. Tønner-Klank et al. [29] showed that appropriate composting can eliminate many human pathogens in different types of compost, as the temperatures attained (50°C to 70°C) during treatment kill enteric microorganisms.

With regard to the length of thermophilic periods, the composting temperature must exceed 45°C for at least three consecutive days to destroy pathogenic organisms and thus meet disinfection requirements [30]. The results showed that the total duration of thermophilic temperatures in this experiment (intensive phase plus maturation phase) was > 3 d. This finding indicated that the duration of the thermophilic stage was sufficient to kill pathogens and meet the disinfection requirements.

By using the new technology, the temperature remained high and steady in the thermophilic temperature range for 24 d and 12 d in the intensive phase and maturation phase, respectively, as the GORE(R) cover membrane completely enclosed the windrow, retaining heat. This technology resulted not only in more rapid attainment and prolongation of thermophilic temperatures but also in the creation of two thermophilic temperature peaks (one during the intensive phase and one during the maturation phase); the main consequence of this was more rapid decomposition of organic waste. El Fels et al. [24] and El Hayany et al. [31] stated that traditional composting requires 180 d and 105 d, respectively, to produce a mature product; two-stage composting consisting of the use of an aerated windrow under a semipermeable film and in the second stage a static open windrow requires 190 d [11]. However, the proposed new technology shortens the SS composting time significantly, producing mature compost in only 49 d.

3.2. Evolution of pH and Conductivity

3.2.1. pH variation

Changes in pH and EC were monitored during the composting of SS mixed with GW. During the first week of composting, the pH value decreased from 7.0 to 6.1 (Fig. 3), which could be due to production of organic acids such as acetic acid and butyric acid from microorganism activity during the degradation of easily degradable compounds, or due to the loss a large quantities of carbon dioxide during the composting process [32]. The decrease in pH could also be due to a reduction in the buffering capacity of the system derived from volatilization of ammonia in the thermophilic phase [33]. Normally during SS composting processes, NH₄⁺ volatilization takes place coincidentally with high temperatures and lower initial CN ratios, thereby reducing the agronomic value of the compost and generating undesirable odours [34]. NH₄⁺ loss during composting ranges from 10% to 76% of TN loss [35]. Advanced compost technology to reduce TN loss is thus needed. The GORE(R) cover membrane inhibited NH₄⁺ emissions as some NH₃ absorbed by the water layer created on the inner surface of the cover, and as a result nitrogen conservation was achieved through the transformation of reduced ammonia [15].

The increase in pH from 6.1 to 7.3 (Fig. 3) during the ensuing 3 w of composting (d 7 to 28 of the intensive phase) can be explained by the production of ammonia during ammonification and the mineralization of organic nitrogen, which releases those bases already present in organic waste [24]. Vergnoux et al. [36] showed that a higher oxygen concentration resulted in more rapid acid decomposition and thus a faster increase in pH. Baeta-Hall et al. [37] and Hachicha et al. [38] also showed that increase in pH may occur as a result of the mineralization of OM and the decomposition of acids containing carboxylic and phenolic groups. After the observed increase, during days 28 to 42 of the maturation phase, the pH of the mixture stabilized at approximately 7 (neutral). Zenjari et al. [39] and El Fels et al. [24] showed that the stabilization of pH at near neutral values during composting results from the generation of humic substances, which act to increase buffering capacity. During the final week of the maturation phase (days 42 to 49), the pH decreased to 6.9, which remained constant at the end of composting; this was the result of compost maturation under aerobic conditions, the generation of humic acids [38, 40], and H⁺ release as a result of nitrification by nitrifying bacteria during the later stages of composting [33]. The final pH values of the composts were 6.9, which matches the recommended pH for matured compost products [41].

3.2.2. EC variation

EC indicates the degree of compost salinity and the quantity of ions in the final composting product; this parameters reflect the potential product phytotoxicity. EC increased sharply from 1.7 mS cm⁻¹ to 3.1 mS cm⁻¹ (Fig. 3). Huang et al. [32] showed that an increase in EC could be due to the release of mineral salts, such as phosphate and ammonium ions, occasioned by the degradation of organic materials. Additionally, concentration effects resulting from OM loss and water evaporation due to high temperatures can increase EC [42].

A similar EC increase observed by Zhang et al. [43] was attributed to water evaporation. The increased content of soluble salts indicated the progressive mineralization of OM [42]. By the end of the composting process, the EC values of the final compost were 3.1 ms cm⁻¹, below 4 ms cm⁻¹ which is commonly regarded as the limit for safe use on plants [44]. This indicates that the compost is safe for most crop growth. However, due to the lack of a definite pattern in the changes in pH and EC over time, these parameters were not considered suitable for monitoring the com-
posting process or for evaluating the stability of the composting material [45].

3.3. OM Loss and Ash Content

Approximately 50% of OM is fully mineralized [46]. The degradation of OM during composting can be estimated based on the loss of OM, and here, OM$_{\text{loss}}$ increased sharply to 52.3% within the first 35 d of composting (Fig. 4) due to the greater availability of substances which are easily biodegradable by microorganisms. It then slowed down, reaching 56.7% at the end of composting due to the depletion of easily biodegradable carbon and the synthesis reactions of the new complex polymerized organic substances (humification), processes which prevail over mineralization during the maturation stage [47]. This transformation matched well with the remarkable reduction in OM, indicating a rapid decomposition rate. Expected OM loss during composting is between 30% and 60% and OM loss > 42% may be accepted as an index value for mature compost [48]. Based on this, the compost could be considered matured during 28 d. Composting is an exothermic aerobic process in which the OM in SS are decomposed and mineralized to CO$_2$ by microorganisms. As a result, a reduction in OM is always observed in SS composting. The higher OM$_{\text{loss}}$ observed in this case could be due to the presence of two thermophilic temperature peaks and the longer thermophilic periods experienced during composting using this new composting technology (Fig. 2). It has previously been found that high composting temperatures accelerate the growth of thermophilic microorganisms, allowing further biodegradation of OM [49].

![Fig. 4. Evolution of OM loss and ash content during composting.](image)

During composting, there was an increase in ash content in the windrow. The ash content increased by 62.3% after 49 d (Fig. 4). Several authors have stated that increased ash content during composting results from the mineralization of OM by microbes [50, 51], and this parameter indicates decomposition and mineralization of the OM, consequently reflecting the degree of stabilization achieved during the process. Final compost with a higher ash content and lower OM is considered mature.

3.4. C/N Ratio

The C/N ratio is one of the most significant parameters used to evaluate the stabilization of compost. In this case, the C/N ratio decreased to reach a value of approximately 6.7 (Fig. 5) after 49 d of composting. The continuous and rapid reduction in the C/N ratio was due to loss of TC and an increase in the proportion of TN due to the concentration effects resulting from the intense biological oxidation of OM over the composting period [32]. The TN value might have been also increased within the compost under the GORR(R) cover membrane due to the contribution of the free-living N-fixing microorganisms that are generated during later stages of the composting process [30]. Several authors have shown no agreement regarding the best C/N ratio for stable compost. However, Chefetz et al. [52], Provenzano et al. [53], and El Fels et al. [24] all state that values near to 10 indicate low microbial activity and result in a stabilized compost. According to Tomati et al. [54], a C/N ratio of between 11 and 22 indicates stabilized compost.

In the present study, the C/N ratio of the final compost reached a value of 6.7, which indicated that compost stabilization was achieved. Using this technology, the C/N ratio reduction rate was higher than the C/N ratios achieved in conventional methods of composting with the same substrate, in which C/N ratios were found reduce to 10.1 [24], 11.7 [48], and 12.9 [55]. This is due to the forced bottom-up aeration system, which improves aeration conditions, accelerates decomposition, and results in a greater loss of carbon as carbon dioxide. The results thus agree with the findings of Guo et al. [18], who demonstrated that higher rates of aeration lead to an enhancement of carbon loss.

![Fig. 5. Evolution of the C/N ratio during composting.](image)

3.5. NH$_4^+$/NO$_3^-$ Ratio

The NH$_4^+$/NO$_3^-$ ratio ranged from 20.3 to 0.1 after 49 d of composting (Fig. 6). The NH$_4^+$/NO$_3^-$ ratio is used to indicate the maturity of compost; a ratio below the limit of 0.16 for composting materials such as SS, municipal solid waste, and pig slurry indicates maturity [47]. The recorded value of approximately 0.1 indicated that the final product reached maturity in this case, and that the substrate had been changed to yield non-phytotoxic compost. Garcia et al. [56] and El Fels et al. [24] showed that a ratio below 1.0 suggests that the final compost has reached maturity. For comparison, the critical limits for maturity during composting of SS by conventional composting technology have been found to be fulfilled after 6 mon [24], 220 d [57], and 135 d [48], while the new composting technology achieved maturity critical limits by the 49th d, implying that the conventional composting technology takes much longer to achieve the index value for maturity than the new composting technol-
ogy, most likely due to the differences in aeration. These results indicate that this new technology is highly suitable for ensuring compost maturity in a shorter time frame due to improved aeration conditions and the flow oxygen throughout the entire composting vessel using forced bottom-up aeration that enhance the oxidation processes, leading to an increase in the intensity of nitrification [58].

3.6. CEC Evolution

During composting, CEC increased substantially from 51.3 cmol kg⁻¹ to 170.3 cmol kg⁻¹ after 49 d (Fig. 7). CEC can be used to evaluate the degree of humification and the nutrient retention capacity of compost [59, 60]. According to Harada and Inoko [20], the CEC of a mature compost should be > 60 cmol kg⁻¹. In the current study, the CEC value of the final product was 170.3 cmol kg⁻¹, which indicates that the compost is mature. Zhang and Sun [60] confirmed that high CEC values are due to larger proportions of carboxyl functional groups in the substrates, while Lax et al. [61] concluded that increases in CEC values during composting could be the result of the accumulation of compounds bearing a negative charge, such as lignin-derived products, carboxyl groups, and phenolic hydroxyl groups. Joseph et al. [62] further showed that the presence of negatively charged groups caused the attraction, retention, and exchange of basic cations, which in turn could increase the CEC and nutrient-holding capacity of the compost. Any increase in CEC during composting is due to the humification process, during which carboxyl and phenolic functional groups are produced [47]. Humic compounds have high capacity to adsorb positively charged ions, which are then easily exchanged with other cations at the same adsorption sites [41].

3.7. UV-visible Spectroscopic Analysis

The evolution of the E₂/₆, E₂/₄, and E₄/₆ ratios provides information on the degree of OM maturity during composting. The E₂/₆, E₂/₄, and E₄/₆ ratios decreased sharply to 5.1, 25.4, and 3.8, respectively, after 49 d of composting (Table S1). These decreases indicate the occurrence of the humification process. The decreases in the E₂/₆ and E₄/₆ ratios at the end of composting demonstrated a strong increase in the humification of OM [55]. Chen et al. [63] used the E₄/₆ ratio as a humification index, and Zbytniewski and Buszewski [22] reported that low E₂/₆ or E₄/₆ ratios reflected high degrees of aromatic condensation and indicated a higher level of organic material humificaiton. E₄/₆ can also be used as an estimator of molecular weight [63]. Guo et al. [64] showed that during the thermophilic stage, rapid breakdown of lignin and quinine moieties occurred as the E₂/₄ ratio decreased, indicating a higher degree of aromatic condensation, as well as a higher level of organic material humificaiton. Therefore, a continuous decrease in E₂/₄ reflects a high degree of aromatic condensation.

3.8. FTIR Spectroscopic Analysis

FTIR spectrometry is a non-destructive qualitative or finger printing method used to characterize the principal classes of chemical groups that make up OM [65], in order to determine the changes seen in OM during composting [66]. The FTIR spectra thus derived are presented in Fig. S1. A very wide band located at 3,460 cm⁻¹ was detected during the process that can be attributed to the stretching vibrations of OH in hydroxyl groups. El Mezouari El Glauoi et al. [66] attributed this band to the hydrogenic vibrations of OH groups of alcohols and to phenols or to the OH of the carboxyl groups (COOH). The interaction of hydroxyl groups with hydrogen bonds explains the wide profile of this band and the fact that the wave number is lower than that of a free OH hydroxyl [24]. El Fels et al. [67] reported that the 3,000-2,800 cm⁻¹ region reflects the hydrophobic properties of aliphatic OM. The peak observed at 2,950 cm⁻¹ is due to methyl derived from methylene C-H aliphatic groups. The intensity of these bands decreases during composting, which is a good indication of the microbial oxidation of OM, especially the aliphatic compounds, during composting [24]. The peak intensity ratio of the bands at 2,920 and 1,640 cm⁻¹ (designated as aliphatic methylene and aromatic C, respectively) is suggested as a meaningful parameter for tracking the biological stability of OM during landfill stabilization [68, 69].

The band located at approximately 1,675 cm⁻¹ showed an increase during composting. El Fels et al. [24] attributed the region from 1,750-1,700 cm⁻¹ to νC = O stretching of the carboxyl group in its nonionized form, and the peaks that appear at approximately 1,650 cm⁻¹ to νC = O of ionized carboxyl (COO⁻). According to Kaiser and Ellerbrock [70], the band at 1,650 cm⁻¹ is associated with the vibrations of νC = C aromatic structures and the antisymmetric vibrations of COO⁻. In a biological specimen study, Maquelin et al. [71] further attributed the 1,675 cm⁻¹ band to the amide I band components resulting from the antiparallel pleated sheets and β-turns of proteins. Pajczkowska et al. [72] observed absorbance bands between 1,680 and 1,630 cm⁻¹ and attributed these to νCOO⁻ in the case of humic acids extracted from sludge at different stages of treatment. An increase in this band thus pro-
vides information on the evolution of humification of OM during composting. Smidt et al. [73] showed that humic acids display a strong band at 1,640 cm$^{-1}$ that increases in intensity during the composting process. The continuous increase in the humic acid content has a positive impact on this band. The bands at 1,470 cm$^{-1}$ are attributed to aromatic benzene compounds. Droussi et al. [74] attributed the region from 1,442-1,472 to C = C stretching vibrations arising from aromatic components. An increase in the intensity of the aromatic absorbance indicates progress in the humification process [24, 66]. The 1,170 cm$^{-1}$ band can be attributed to the presence of a carboxyl functional group in the first, while that seen in the second is probably a characteristic of an ester bond. The 1,160 cm$^{-1}$ band is assigned to the asymmetric stretching of C=O-C of glycosidic linkages [76]. Ouatmane et al. [77] and Wu et al. [69] attributed the 1,165 cm$^{-1}$ band to C=O-C stretching; El Mezouari El Glauoi et al. [66] showed that the latter band could also be used as an indicator of the biodegradation process. The 1,067 cm$^{-1}$ band remained constant during composting. The region at 1,080-1,030 cm$^{-1}$ was attributed to the C-O stretching of polysaccharides or polysaccharide-like substances and the Si-O asymmetric stretch of silicate impurities [78, 79]. Aguelmous et al. [80] observed bands located at 875 and 713 cm$^{-1}$, which suggest the presence of calcium carbonates. The band at 875 cm$^{-1}$ could be attributed to the C-O out of plane vibration of carbonates. Reig et al. [61] attributed the 875 cm$^{-1}$ band to the C-O out-of-plane bending of carbonate. The evolution of each functional group reflects the advanced stage of humification of OM during composting.

3.9. Characteristics of the Final Compost

Compost product can be safely used as organic fertilizer or conditioner once it is mature or stable and does not present toxicity to plant growth [41]. Table S2 shows the main chemical properties of the final composts obtained in this experiment. The final compost product satisfied the threshold levels established in the literature for common maturation indices, suggesting that it can be used as an organic fertilizer for plant growth. These findings indicated that composting was carried out successfully under optimized conditions.

4. Conclusions

The current study indicates that ELS composting technology is an effective method for the disposal of SS waste based on the production of mature compost. The final compost product met the threshold levels established in the literature for the subsequent use of such compost as a soil amendment or as organic fertiliser for soil based on it obtaining the following parameters: pH 7.1-7.7, EC < 4 mS cm$^{-1}$, C/N ratio < 10, NH$_4^+$/NO$_3^-$ < 0.16, CEC > 60 cmol kg$^{-1}$, and OM 33.3-55.4%. This new technology is novel and is extremely effective due to its two thermophilic temperature peaks, as well as rapid onset, and long-duration thermophilic phase. Moreover, the proposed new technology shortens SS composting time to obtain mature compost in only 49 d, unlike conventional composting technology that requires 105-180 d and produces more immature compost. Further studies are recommended to focus on the evolution of microbial communities and enzymatic activities in this new process.

Acknowledgments

This study was conducted with the financial support of the Stipendium Hungaricum Scholarship and the Tempus Public Foundation. I would also like to offer deep thanks to Eng. Zoltan Bernath and Eng. Pádra István from the BÁCSVÍZ for their assistance in the successful completion of the work.
